- > Remote Registry Service, OpenKey

- 1. The client initiates a connection request to the server.
- 2. The server authorizes the request.
- 3. The client requests the opening of a key on the server.
- 4. The server responds with an RPC context handle that references the key.

- 5. The client uses the handle to operate on the key.
- 6. The client sends the desired operation along with the associated parameters.
- 7. The server responds to the request with the requested information.

Operation	Opnum
BaseRegCreateKey	6
BaseRegDeleteKey	7
BaseRegOpenKey	15
BaseRegDeleteValue	8

## Security Context https://msdn.microsoft.com/en-us/library/cc243713.aspx

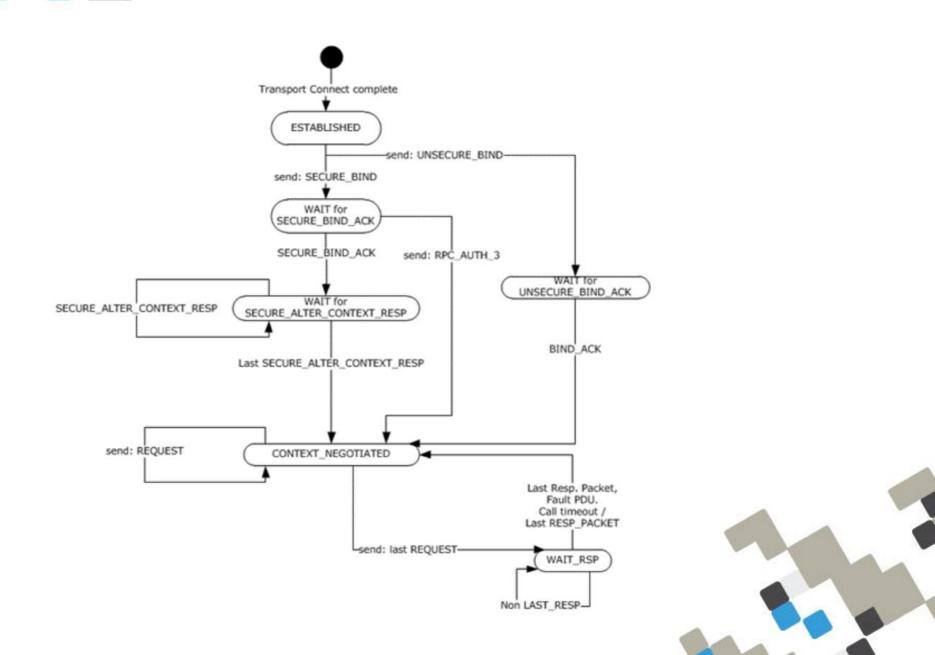

security context: An abstract data structure that contains authorization information for a particular security principal in the form of a Token/Authorization Context (see [MS-DTYP] section 2.5.2). A server uses the authorization information in a security context to check access to requested resources. A security context also contains a key identifier that associates mutually established cryptographic keys, along with other information needed to perform secure communication with another security principal.

- To make secure RPC calls, a security context must be established.
- The scope is the connection.
- Bind/Bind\_ack message exchange with authorization info between the RPC client and server.
- If there is an error: Fault PDU and connection closure.
- Once the context is established, it can be used by RPC and other protocols to make authorization decisions.

https://msdn.microsoft.com/en-us/library/cc243630.aspx#gt\_8a7f6700-8311-45bc-af10-82e10accd331

### Security Context

https://msdn.microsoft.com/en-us/library/cc243724.aspx

## Security Provider

security provider: A pluggable security module that is specified by the protocol layer above the remote procedure call (RPC) layer, and will cause the RPC layer to use this module to secure messages in a communication session with the server. The security provider is sometimes referred to as an authentication service. For more information, see [C706] and [MS-RPCE].

- The client begins by requesting an authorization token from the security provider (NTLM).
- This token represents the client's identity and can be used to make authorization decisions.
- Additionally, RPC can use the security context to create a logical chain of information protected against tampering and disclosure. .

## Authentication Levels

The amount of protection applied depends on the authentication level for the security context requested by the client when the security context is created. The authentication level is applied in two dimensions:

Description
No protection is established.
Provides verification of the client and server identities, protects against replay attacks, but no measures are applied per PDU (Protocol Data Unit).
Provides integrity for the first fragment of each call.
Provides protection against replay and out- of-order attacks at the PDU level but does not protect against modification at the PDU level.
Provides integrity (signing) at the PDU level.
Provides integrity (signing) and confidentiality (encryption) at the PDU level.

In case of catastrophic errors (such as an out of memory condition or buffer overrun), a server MAY send a fault PDU or just close the connection. For information on client and server state machines, see sections 3.3.2 and 3.3.3.

- If the security provider indicates an error, the RPC runtime MUST take recovery action depending on whether this is the client or server.
  - If this is the client, the RPC runtime discards the security context and MUST NOT send any further PDUs on that connection. It SHOULD close the connection unless it is expecting responses on a multiplexed connection, as specified in section 3.3.1.5.8, in which case it SHOULD set the Activity's **Discard** flag to TRUE. If it does not wait for all responses on a multiplexe connection, it MUST provide indication in an implementation-specific way to upper layers that the outstanding calls have failed.

The dce\_c\_authn\_level\_none Protection Level The auth\_value is null; the entire authentication verifier may be omitted.

http://pubs.opengroup.org/onlinepubs/9629399/chap13.htm

- 1. When the client initiates a connection with the server using the Remote Registry Protocol, a security context with an authentication level of 6 (Dce\_c\_auth\_level\_pkt\_privacy) is associated.
- 2. During the first interaction with the remote machine's registry, an error occurs that forces the security context to be discarded.
- 3. The client initiates a new connection, this time requesting an authentication level of 1 (dce\_c\_auth\_level\_none) from the security provider, which results in no integrity or confidentiality protection for the PDUs.

### WinregMITM

#### https://github.com/shramos/winregmitm

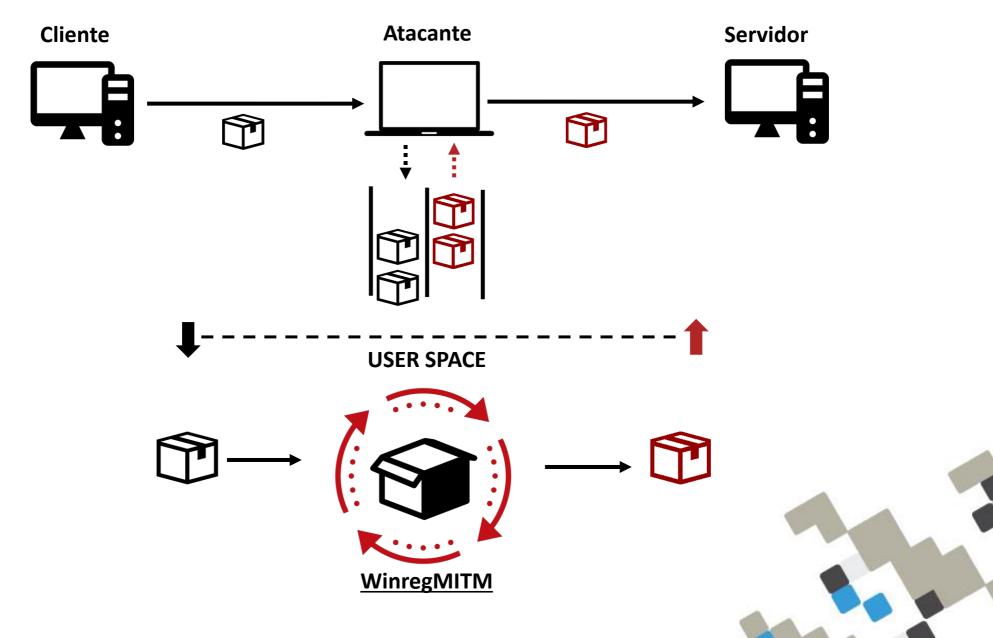

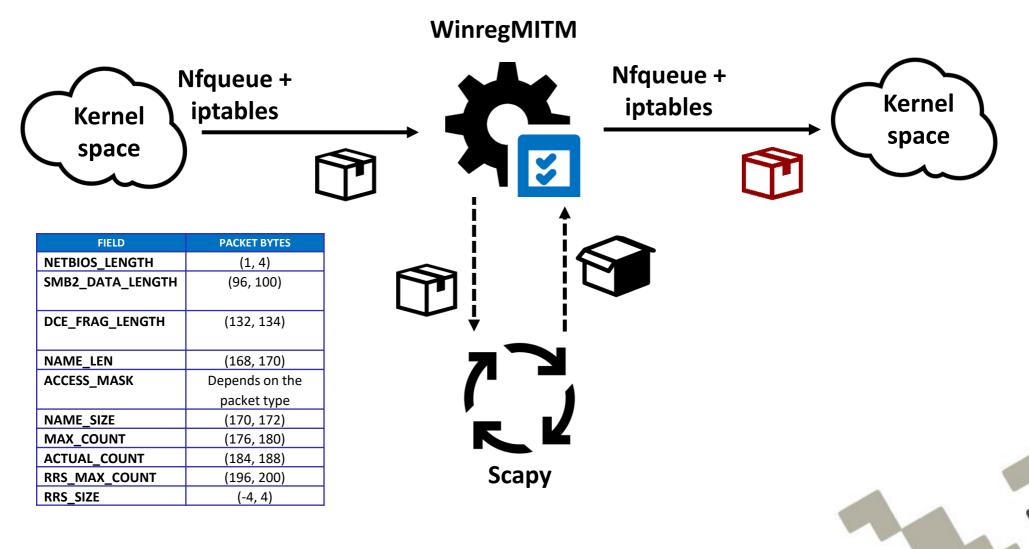

- 1. Intercept the communication between the client and the server
- 2. Intercept the packets and forward them to user space so they can be filtered and modified by our tool.
- 3. Filter specific packets and interpret their bytes.
- 4. Modify the fields of interest.
- 5. Recalculate all control fields of the WINREG layer and the preceding layers.
- 6. Reconstruct the packet and resend it.

https://github.com/shramos/winregmitm https://github.com/secdev/scapy/tree/master/scapy http://www.netfilter.org/projects/libnetfilter\_queue/index.html https://pypi.python.org/pypi/NetfilterQueue

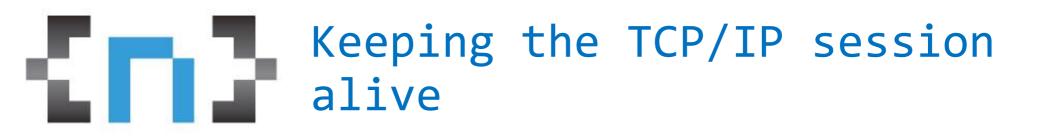

### Am I missing something?

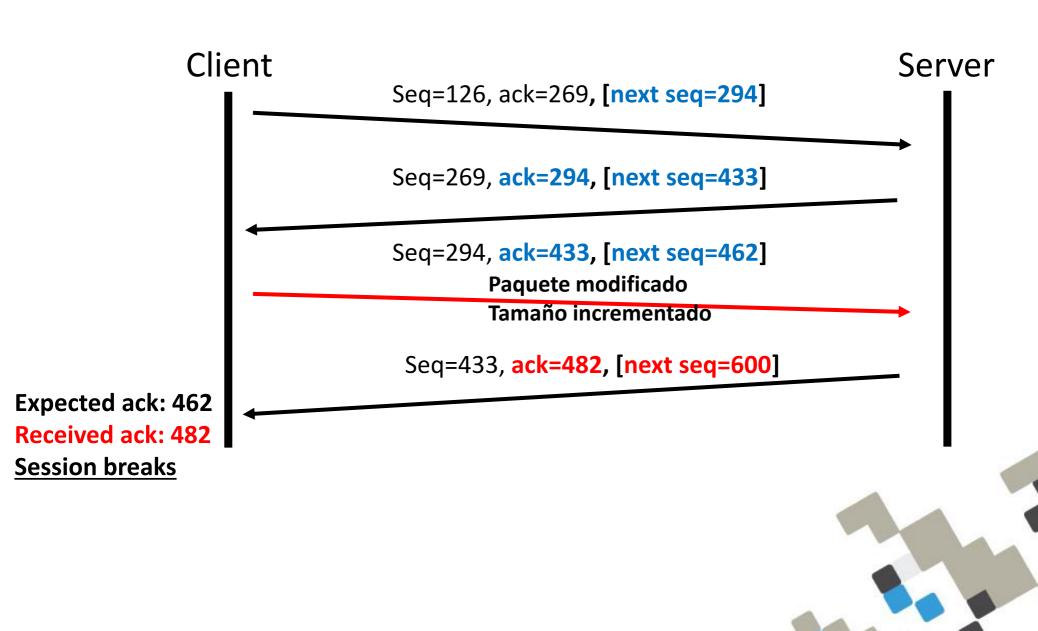

- Most popular tool to access the log of a remote machine
- I modify a packet, recalculate all fields, resend the packet, and the session breaks. Why?

#### Next sequence number = Actual sequence number + TCP payload length (\*)

(\*) TCP payload length = length(IP) - length(IP.header) - length(TCP.header)

- 1. ARP spoofing between the Client and the Server
- 2. We run WinreMITM and start monitoring user activity on the remote machine.
- 3. We intercept and modify an OpenKey packet and a SetValue packet to insert a payload into a specific registry branch of the remote machine, in this case: HKEY\_CURRENT\_USER\Software\Microsoft\Windows\CurrentVersion \Run
- 4. When the user restarts the machine, our payload will execute, performing a Fileless UAC bypass and returning a remote connection with maximum privileges to the attacking machine.

- The Windows Remote Registry Protocol is not always unencrypted and unsigned.
- There are two use cases related to encryption and integrity control of the protocol:
- 1. Authentication is performed with a user whose name or password differs from that of the remote machine:
  - User and password must be provided.
  - The authentication level is 1 (no encryption or signing).
- 2. Authentication is performed with a user who has the same name and password as the remote machine:
  - User and password are not required.
  - The authentication level is 6 (encrypted and signed).

• Failure during the first access to the remote registry: In the next connection, a security context is established with authentication level 1.

### Forcing the security context

In case of catastrophic errors (such as an out of memory condition or buffer overrun), a server MAY send a fault PDU or just close the connection. For information on client and server state machines, see sections 3.3.2 and 3.3.3.

https://msdn.microsoft.com/en-us/library/cc243713.aspx

- We extract the bytes of the \*\*DCE/RPC layer\*\* from the Fault packet sent by the server to the client in sessions without encryption or signing.
- 2. We replace the \*\*DCE/RPC layer "on-the-fly"\*\* in the packet where the server accepts authentication level 6 in an encrypted and signed session.
